Abstract—The Architecture Analysis and Design Language (AADL) is an SAE International Standard dedicated to the precise modeling of complex embedded systems, covering both hardware and software concerns. Its definition relies on a precise set of concepts inherited from industry and academics best practice: clear separation of concerns among layers, rich set of properties to document system metrics and support for many kind of analysis: scheduling, safety and reliability, performance, but also code generation.

In this tutorial, we provide an overview of AADLv2 and illustrate how several analyses can be combined on an illustrative example: a UAV platform.

I. OVERVIEW OF THE AADL

The “Architecture Analysis and Design Language” AADL is a textual and graphical language for model-based engineering of embedded real-time systems. It has been published as an SAE Standard AS-5506B [7]. AADL is used to design and analyze the architecture of embedded real-time systems.

AADL allows for the description of both software and hardware parts of a system. It focuses on the definition of block interfaces, and separates the implementations from these interfaces. It can be expressed using both a graphical or a textual syntax. From the description of these blocks, one can assemble blocks to represent the full system.

An AADL model can incorporate non-architectural elements: embedded or real-time characteristics of the components (execution time, memory footprint, ...), behavioral descriptions, ... Hence it is possible to use AADL as a backbone to describe all the aspects of a system. Let us review them:

An AADL description is made of *components*. The AADL standard defines software components (data, thread, thread group, subprogram, process) and execution platform components (memory, bus, processor, device, virtual processor, virtual bus) and hybrid components (system).

Each component category describe well identified elements of the actual architecture, using the same vocabulary of system or software engineering:

- *Subprograms* model procedures like in C or Ada. *Threads* model the active part of an application (such as POSIX threads). AADL threads may have multiple operational modes. Each mode may describe a different behaviour and property values for the thread. *Processes* are memory

spaces that contain the *threads*. *Thread groups* are used to create a hierarchy among threads.

- *Processors* model micro-processors and a minimal operating system (mainly a scheduler). *Memories* model hard disks, RAMs, *buses* model all kinds of networks.
- *Virtual bus* and *Virtual processor* models logical point of view of hardware components. A virtual bus is a communication channel on top of a physical bus; a virtual processor denotes a dedicated scheduling domain inside a processor (e.g. an ARINC653 partition running on a processor).
- Unlike other components, *Systems* do not represent anything concrete; they combine building blocks to help structure the description as a set of nested components. *Packages* add the notion of namespaces to help structuring the models. *Abstracts* model partially defined components, to be refined during the modeling process.

Component declarations have to be instantiated into sub-components of other components in order to model an architecture. At the top-level, a system contains all the component instances. Most components can have subcomponents, so that an AADL description is hierarchical. A complete AADL description must provide a top-most level system that will contain certain kind of components (*processor*, *process*, *bus*, *device*, *abstract* and *memory*), thus providing the root of the architecture tree. The architecture in itself is the instantiation of this system, which is called the *root system*.

The interface of a component is called *component type*. It provides *features* (e.g. communication ports). Components communicate one with another by *connecting* their *features*. A component type can have several implementations. They describe the internals of the components: subcomponents, connections between those subcomponents, ...

An implementation of a thread or a subprogram can specify *call sequences* to other subprograms, thus describing the execution flows in the architecture. Since there can be different implementations of a given component type, it is possible to select the actual components to put into the architecture, without having to change the other components, thus providing a convenient approach to configure applications.

The AADL defines the notion of *properties* that can be attached to most elements (components, connections, features,
